What the HAK? 
Estimating Ranking Deviations in Incomplete Graphs*

ABSTRACT
Most real-world graphs collected from the Web like Web graphs and social network graphs are incomplete. This leads to inaccurate estimates of graph properties based on link analysis such as PageRank. In this paper we focus on studying such deviations in ordering/ranking imposed by PageRank over incomplete graphs. We first show that deviations in rankings induced by PageRank are indeed possible. We measure how much a ranking, induced by PageRank, on an input graph could deviate from the original unseen graph. More importantly, we are interested in conceiving a measure that approximates the rank correlation among them without any knowledge of the original graph. To this extent we formulate the HAK measure that is based on computing the impact redistribution of PageRank according to the local graph structure. Finally, we perform extensive experiments on both real-world Web and social network graphs with more than 100M vertices and 1B edges as well as synthetic graphs to showcase the utility of HAK.

Graph Analysis; Incomplete Subgraphs; PageRank

1 INTRODUCTION
Most real-world graphs collected from the Web like Web graphs and social network graphs are incomplete or in other words their graph topology is not known in entirety [13, 28]. Especially if not crawled for a particular purpose or subset, but extracted from existing crawls, such as Web archives. The goal of Web archive crawlers is to capture as much as possible starting from some seed set within some national domain or even broader, given the available but limited resources [9]. Incompleteness is an inherent trade-off already in the design decision of such an archive [14]. Complicating matters further, Web archives are often not constructed in one piece but by merging partial crawls [19]. Additional reasons for the incompleteness in Web archives include the restrictive politeness policies (i.e., robots.txt) or random timeouts of Web servers. Several studies on this topic have shown that incompleteness is indeed a common issue [1–3, 22], inevitably affecting the graphs extracted from such crawls as well.

*This work is partly funded by the European Research Council under ALEXANDRIA (ERC 339233)

As a result, important graph properties and measures used for link analysis and structural characterization like authority of vertices might be inherently flawed or exhibit deviations from their original values. This is commonly observed where users are typically agnostic to the incompleteness of the obtained graph, hoping that the input graph is a reasonable representative sample of the underlying (unseen) original graph. Some of the well-known measures for computing authority of vertices or relative ordering of vertex authorities based on random walks are PageRank [32] and its variants [15, 18, 25].

As an example, consider PageRank computed over the .gov Web graph that we will analyze in detail later in this work. Here, the women.nasa.gov (Women@NASA) page has a high PageRank value and is subsequently found within the top 300 pages. However, on a closer examination we observe that most of its PageRank is contributed by an in-link from the highly popular NASA homepage (nasa.gov). If for some reason this particular in-link is not crawled, e.g., due to a temporary downtime or the decision by NASA to exclude their homepage from being crawled, this would cause a large decrease in its PageRank and hence a severe rank deviation in the obtained crawl.

One might argue that this is an unlikely case since important pages enjoy a high priority and are therefore commonly crawled, but this might not always be the case in reality. To support our claim we performed the following experiment. We ranked pages in a graph constructed from a .de Web archive in 2012 based on (1) inlinks and (2) PageRanks. The above mentioned graph considered only links that emerged in 2012 [20]. We then checked if the top ranked pages in this incomplete graph were indeed archived in that year. Our experiments show that from among the top 1000 pages, ranked according to inlinks, roughly 30% are contained in the archive. According to PageRank rankings, less than 20% of the top 1000 pages are contained in the archive. With this small experiment we show that high priority vertices can indeed be missed in real world crawls, which can further cause a rank deviation in the obtained incomplete graph.

We, therefore, study the deviation in orderings/rankings imposed by PageRank over incomplete graphs. Vertices in our input crawls are either completely crawled (all neighbors are known) or are uncrawled (none of their neighbors are known), which we refer to as ghost vertices. Based on this, the research questions we ask are the following:

• **RQ I:** Do incomplete real-world graphs show a deviation in their PageRank orderings when compared to full network topology?
• **RQ II:** How can we reliably measure the extent of such ranking deviations for incomplete graphs?

Towards these, we perform extensive experiments on both real-world Web and social network graphs with more than 100 million vertices and 10 billion edges. We first establish empirically that real-world networks indeed show a deviation in their PageRank orderings when not crawled completely compared to the complete graph (RQ I). We observe ranking correlations (measured by Kendall’s Tau) dropping down to 0.55 on Web graphs when only 50% of it is crawled. Second, users and applications that use rankings induced by PageRank as a feature for downstream ranking and learning tasks would naturally be interested in estimating such a deviation from the (incomplete) input graph at hand as a measure of confidence. Therefore, as an answer to RQ II, we propose a measure called HAK (an acronym of the authors’ names) that estimates the ranking deviation of an incomplete input graph when compared to the original graph.

2 RELATED WORK

Ng et al. [31] analyzed the conditions under which eigenvector methods like PageRank and HITS can provide reliable rankings under perturbations to the linkage patterns for a given collection. In particular for PageRank they showed that, if perturbed or modified web pages, i.e., links from the page are removed or are not followed, did not have a high PageRank score in the original graph, then the new PageRank score will not be far from the original. However, this would change when top pages in the crawl are perturbed. In particular, when some high ranked page is missed as we discussed in the previous section, the resulting PageRank rankings will be highly unstable. Moreover their paper discusses the ranking deviations only for the top 10 items in either of the considered rankings though. We on the other hand, provide a quantitative evaluation using Kendall’s Tau for a much larger fraction of the graph, which is crucial for the use of PageRank in Information Retrieval scenarios where a selected set of relevant documents are ranked. Further, we provide a measure to estimate ranking deviations of vertices in the given graph with respect to their orderings in the original unmodified graph.

Boldi et al. [6] also show the paradoxical effects of PageRank computation on Web graphs. In contrast to our work though, they discuss a measure of effectiveness for crawl strategies based on whether the graph obtained after a partial visit is in some sense a CRP. We provide a measure to estimate ranking deviations of vertices in the context of incompleteness in graphs due to their collection process.

Definition 3.1 (Target graph). The subset of vertices (with the induced edges) of a larger graph (e.g., the Web) that is theoretically reachable by a crawler given its seeds, e.g., a domain, a top-level domain, or all webpages that belong to a certain topic in case of focused crawlers. This graph would be available if every link was followed and every page captured by the crawler, illustrated by the target in Figure 1.

Definition 3.2 (Crawled graph or Crawl). The (incomplete) graph derived from the set of webpages that have actually been visited by the crawler, discovered/linked yet uncrawled pages are not included. This subset of the target graph is illustrated by the crawl in Figure 1.

Definition 3.3 (Ghost vertex). Although a hyperlink on a crawled page points to another page that belongs to the target graph, there is a chance the crawler never visited and saved that page, i.e., it is not part the crawl. Such a page or vertex is referred to as ghost vertex, shown by the gray vertices outside the crawl in Figure 1.

Ranking Deviations. The deviation among two rankings induced by PageRank is a global objective, independent of a specific query. Hence, local or relevance-based measures such as nDCG are not applicable here. The most common metrics to quantify rank correlation are Spearman’s Rho and Kendall’s Tau, which are both similar as they are special cases of a more general correlation coefficient.
and measure relative displacements. In this work, we use Kendall’s Tau [24], ranging from $[-1, 1]$, with 1 corresponding to a perfect rank correlation, 0 corresponding to no correlation and $-1$ to a perfect inverse correlation. This is used to compare the correlation/divergence of rankings computed on the vertices of a crawl $G_C$ with respect to that of the target graph $G_T$.

In Figure 2 we provide a few examples of possible graph structures, where partial knowledge of the graph may affect the ranking returned by the PageRank values. We remark that in the next sections, we will also provide empirical evidence, supporting the fact that there exists a ranking deviation in crawls of some real-world graphs. In the first subfigure (a), we show the positive case of a DAG where the partial knowledge of the graph will not cause any ranking deviations. As only the topmost vertices shown here receive significantly more links than the others, these are also the most important vertices. It is easy to see here that generating a crawl from this structure by removing some vertices will not cause any significant changes in the ranking orderings of the crawl. In the next subfigure (b), a backlink has been introduced (left) that feeds back the importance of a top most page to a previously unimportant page and its successors. This importance gets propagated through the cycle which has been created due to the inserted backlink. In the next subfigure (c), we illustrate the case of a crawl in which vertices are removed uniformly at random. The chances here are that primarily unimportant vertices are removed, which would still not cause much deviations in the ranking orderings. Finally, if we remove any vertex from the cycle as shown in subfigure (d), its successor vertices drastically lose in importance and hence, the ranking among the pages in the crawl changes noticeably.

### 4 THE HAK MEASURE

With our measure, we estimate quantitatively how reliable a crawl is with respect to the relative ordering of the PageRank values on its vertices compared to the corresponding target graph. To this end, we first try to estimate the size of the target graph: Given the crawled vertex set and the distinct hyperlinks on the corresponding webpages, some of which are pointing to an uncrawled page (ghost vertex), how big is the target graph or a subgraph that would potentially impact or contribute to the PageRank values of the vertices in the crawl? We show that for simple crawling strategies where it can be assumed that each vertex is part of the crawl independently from all other vertices with some sampling probability $p_s$, the size of the target graph can be estimated in terms of a very simple property of the crawled vertices, namely, the fraction of its crawled neighbors, referred to as fidelity. Secondly, we try to estimate the impact exerted by the vertices in the target graph on the crawled vertices, which we in turn use to estimate the number of discordant pairs in the expected rankings, like in Kendall’s Tau.

Let $C$ denote the set of vertices of the crawl graph and let $n$ be the number of vertices in this graph. The main steps in our computation are as follows:

1. Estimate the size of the target graph by using connectivity properties of the crawl. Let $T$ represent the set of vertices in this target graph.
2. Estimate the impact (as functions of PageRank) of the vertices in $C$.
3. Assume that the vertices in $T$ exert similar impacts on other vertices.
4. Estimate the number of discordant pairs due to impacts exerted by vertices in $T - C$ on vertices in $C$.

#### 4.1 Estimating the Target Graph

Let $N$ denote the number of vertices in the target graph. In this section we will estimate the value of $N$ under the simplified assumption that the crawl is constructed by sampling vertices from the target graph independently and uniformly at random with some probability $p_s$. Note that if $p_s$ is known, one can easily estimate $N$ as $\frac{n}{p_s}$. We therefore first estimate $p_s$ from the connectivity of the crawl, using a property that we refer to as fidelity: For any vertex $v \in T$, we define fidelity ($\gamma(v)$) as the ratio of its immediate neighbors in $C$ to its total out-degree (number of distinct hyperlinks on a webpage pointing to vertex in $T$). Let $d_v$ count the number of vertices $v' \in C$ reachable from $v$ in one step. $d_v$ denotes the total out-degree of $v$ in the target graph. This results in the following definition:

**Definition 4.1 (Fidelity).** The fidelity of a vertex $v \in T$, $\gamma(v)$, is given by $\gamma(v) = \frac{d_v(v)}{d(v)}$ and the average fidelity of all vertices in $C$ is $\gamma(C) = \frac{\sum_{v \in C} \gamma(v)}{n}$.

With $p_s$ as the sampling probability, $p_s \cdot N$ would be the number of vertices in the crawl. Hence, using the observed average $\gamma(C)$ and the observed size of the crawl ($n$), we approximate $N$ as $\frac{n}{\gamma(C)}$.

#### 4.2 PageRank and Impacts

Despite its incompleteness, PageRank can be computed on the crawl graph by treating the ghost nodes as dangling nodes. We use the personalized variant of PageRank for this, starting from
the available nodes in $C$ as seeds (s. Section 5). Given this, for any vertex $v$ in the crawl $C$, let $\pi(v)$ denote the value computed by PageRank and let $N(v)$ denote the set of succeeding neighbors of $v$, reachable from $v$ in one step, hence $d(v) = |N(v)|$. PageRank of any vertex $u$ can now be considered as:

$$\pi(u) = \sum_{v \in N(v)} \frac{\pi(v)}{d(v)}$$

Based on these considerations, we introduce a new property, referred to as **impact**. The impact of a vertex $v \in C$ on one of its neighbors $u \in N(v)$ is defined as:

$$Im(v, u) = \frac{\pi(v)}{d(v)}$$

Hence, the total impact on any vertex $u \in V$, received from all its incoming edges, is $\frac{1}{\pi(u)} \sum_{v : u \in N(v)} \frac{\pi(v)}{d(v)}$, which is always 1. This implies that any extra impact of $x$ on a vertex will increase its PageRank by $x$ times the current PageRank. The total impact of a vertex $v$, $Im(v)$ is then defined as:

$$Im(v) = \sum_{u \in N(v)} Im(v, u) = \sum_{u \in N(v)} \frac{\pi(v)}{d(v)} \cdot \frac{1}{\pi(u)} = \frac{1}{d(v)} \sum_{u \in N(v)} \frac{\pi(v)}{\pi(u)}$$

We denote the average of impacts of vertices in $C$ by $Im(C)$, i.e.

$$Im(C) = \frac{\sum_{v \in C} Im(v)}{n}$$

4.3 Estimating the Impact of Ghost Vertices

We next compute the impact that could have been exerted by the ghost vertices on the crawled vertices, if the graph was complete and the ghost vertices existed. In a setting like ours, where the (personalized) PageRank is computed from the perspective of the known crawl (see above), the ghost nodes cannot have a bigger impact on the crawl than previously leaked to them. Therefore, we build on the assumption that the impact of each vertex in the complete target graph $T$ is on average the same as for the crawl: $Im(C)$. Hence, we approximate the impact exerted by ghost vertices only as follows:

$$I = |T - C| \cdot Im(C) = n \left( \frac{1}{\gamma(C)} - 1 \right) \cdot Im(C)$$

Some of this extra impact, generated due to ghost vertices, will be acquired by some or all of the vertices in $C$, changing their PageRank value accordingly. This is what eventually will lead to the deviation in rankings, measured by Kendall’s Tau as the number of pairs of each two crawled vertices $(v, u) \in C \times C$ for which the order differs, i.e., discordant pairs, or is preserved, i.e., concordant pairs. Since HAK is meant to predict the deviation as assessed by Kendall’s Tau, we also estimate both these classes of pairs in order to compute HAK.

The impact of the ghost vertices can be divided among the vertices of the crawl in several ways. For example, it can happen that the vertex with the lowest PageRank receives the total impact, increasing its PageRank by a large factor. In this case the number of discordant pairs is upper bounded by $n - 1$. Moreover, we know from [31] that vertices with low original PageRank scores will also have a low PageRank value in slightly modified graphs. Therefore, the effect of the loss of information because of incomplete crawls is observed mostly on the PageRanks of the nodes higher in the original ranking. We checked experimentally several variants for impact distributions and the best variant, which is affirmative with our

tests on real-world and synthetic graphs, is to distribute the total impact $I$ equally among $I$ vertices. Hence, the expected number of impacted vertices that belong to the crawled set will be:

$$I = I \cdot \gamma(C)$$

In the worst case, each of these impacted vertices will result in forming a discordant pair with each of the unaffected vertex, resulting in a number of discordant pairs of $D = (n - 1) \cdot I$. Based on that, HAK is computed with respect to Kendall’s Tau as follows:

$$HAK = \frac{\# \text{concordant pairs} \cdot \# \text{discordant pairs}}{\# \text{total pairs}} = \frac{n(n-1)}{2} - D - D = 1 - 4 \cdot \frac{D}{n(n-1)}$$

5 EXPERIMENTS

To validate our research questions enumerated in Section 1 we consider a host of large real-world graphs as well as synthetic graphs of different structures and carefully consider crawling strategies over them. In what follows we first describe our setup and rationale for our evaluation, before we discuss the results of our HAK experiments.

5.1 Experimental Setup

The described experiments require the availability of crawls as well as the complete target graphs that these crawls were derived from. This is necessary in order to compute how the rankings on both graphs differ and to evaluate the performance of HAK to estimate this deviation. In reality, neither obtaining the complete target graph is possible nor the actual crawl policy can be determined accurately. To this extent, we consider very large (as complete as possible) real-world graphs under the assumption that those graphs are complete (Sec. 5.1.1). We additionally simulate alternative topological structures by generating synthetic graphs (Sec. 5.1.2). We then simulate crawls on these graphs using different crawling strategies (Sec. 5.1.3). For all graph and crawl combinations we ran PageRank on both graphs (crawl and target graphs) and compared the rankings using Kendall’s Tau to evaluate HAK (Sec. 5.1.4).

5.1.1 Real-World Graphs. The experiments on real-world graphs were run on a computer cluster using Apache Spark and its graph processing framework GraphX [36]. Loading the graphs locally on a single server was impossible with our available infrastructure because of their sizes of up to more than 100M vertices and 10B edges. As discussed earlier, we obtained multiple large real-world graphs that themselves were incomplete and considered them as target graphs by discarding edges that connect to ghost vertices. The following graphs were analyzed and are summarized in Table 1:

- **GOV**: This graph is based on crawled webpages provided by the Internet Archive [33]. It was extracted from the latest captures of all their archived webpages under the .gov top-level domain (TLD) from 2005 to 2013.
- **DE**: Like GOV, this .de TLD graph was also extracted from webpages archived by the Internet Archive, crawled in 2012 and generously provided to us in the project ALEXANDRIA².

5.1.2 Synthetic Graphs. In order to investigate ranking deviations caused by different crawling strategies on different graph topologies, we ran a more comprehensive set of experiments on smaller, synthetically generated target graphs. This allowed for more extensive experimentation as the experiments could run locally on a single server, using the NetworkX graph analysis framework [16]. All synthetic graphs that we studied in this work (cp. Table 2) were generated with 10,000 vertices to be reasonably sized for a thorough analysis.

The graphs were constructed using well-known graph generators, except for FFBacklinks, which is an extension by us to the ForestFire model. Although Forest Fire graphs include cycles, the model never generates backlinks from the early created vertices, which are more likely to receive many in-links over time, to newer ones. However, these links are common on the Web, where already prominent pages add links to less important ones, having a strong impact on the value propagation in PageRank (s. Sec. 3). In this graph, we added such edges between 0.05% of all pairs of an old and young vertex.

5.1.3 Seed Selection and Crawling. Crawling can be considered a special case of network sampling from a more practical point of view, where subsequent vertices can only be chosen from already discovered ones or seeds. Maiya and Berger-Wolf [30] define this type of sampling as link-trace sampling and give a nice overview of available models for this behavior. Naturally, such approaches commonly exhibit BFS-like (Breadth-First Search) growth, but feature different strategies to prioritize or select the next vertices to be crawled. These variations determine the probability of a vertex to be part of the final sample.

How we model crawls. Although most crawlers employ BFS-like traversals, there are practical constraints like random timeouts and crawl restrictions on websites that make it hard to model crawls perfectly. Therefore, we focus on the most impartial strategy, which is vanilla BFS, but explicitly produce partial crawls by dropping x% of the vertices of the input graph (where x ∈ {10, 20, 30, 40, 50}). We refer to this percentage as the block fraction and the remainder as desired fraction.

Statistics about the target graphs (\#V_target and \#E_target), which are potentially reachable from the seeds by not blocking any vertices are shown in Table 1. Additionally, we discuss a few edge cases by looking at slight variations of BFS as well as SEC with the synthetic graphs. Due to their scale it was computationally infeasible for us given our cluster setup to analyze these on real-world graphs as well. More details on the crawling strategies as well as our seed selection are given in the Appendix A.

5.1.4 Evaluation strategy. The objective of this evaluation is to assess ranking deviations as quantified by Kendall’s Tau (cf. Sec. 3) for rankings induced by PageRank, computed on a complete target graph vs. an incomplete crawl and compare it against our HAK measure, which is designed to yield values on the same scale. For this, we focus only on high-ranked vertices, as these are typically more interesting in most practical scenarios [31]: Firstly, because there is no tangible score difference between the PageRank values of the tail vertices. Secondly, ranking deviations in authoritative vertices are typically considered more severe than among the tail ones. Since Kendall’s Tau makes no distinctions where rank reversals take place, we compared the ordering among the top 30%, top 50% and top 70% vertices of the crawl and target graph that appeared in both graphs according to the corresponding PageRank values. This also helps us characterize where the rank reversals indeed do appear.

The rankings for each of the graphs are computed based on the PageRank values. While we employed the regular version PageRank on the crawl (with added ghost vertices as sinks), we used the personalized variant of PageRank for running it on the target graph.

In this version, the algorithm is personalized to a set of vertices, which constitute the starting points as well as teleportation destinations in the algorithm [32]. The resulting PageRank values can be interpreted as their importance with respect to these vertices or the domain represented by the crawl. Both variants of PageRank ran for 30 iterations with the damping factor parameter set to the frequently cited value of 0.85.

5.2 Crawls and Ranking Deviations in Graphs

In this section, we aim to answer RQ I and justify the need for estimating ranking deviations before employing PageRank for incomplete graphs. In particular, we argue about the results where we witness noticeable ranking deviations of partial crawls with respect to target graphs.

We clearly observe that all real-world graphs exhibit a decreasing \( \tau \) with increasing block fraction (see Figure 3). Most acutely, \( \tau \) decreases to 0.55 for the GOV. Synthetic graphs like \( G_{m,p} \) and FFBacklinks (first and last row in Figure 4) exhibit a similar trend with \( \tau \) decreasing for increasing block fraction. On the other hand, for the ScaleFree (second row) and ForestFire graphs (third row), we do not witness much change in the ranking orderings, except in the BFS crawls.

A detailed study of the crawls reveals the reasons for such disparate trends for ScaleFree and ForestFire: the crawling strategy combined with the underlying structural properties of the graph sometimes lead to extremely small crawls (\( n < 1,000 \)), much below the desired fraction (cp. Sec. 5.1.3). First, we observe a scarcity of backlinks in...
We argue that most of the real-world graphs will not be DAG-like (reported in Figures 3 and 4. We recall that the main assumption is that each of its vertex has the same fraction of crawled neighbors as the crawled vertices (computed by fidelity). This assumption would not be followed by target graphs, which for example are DAG-like, because the ghost vertices there might not have edges back into the crawl. We remark that HAK cannot identify structures in target graph which are not similar to the crawl, yet leading to severe ranking changes in the crawl. For instance, consider a very small crawl with a very high fidelity and low impact. In such a case HAK would always estimate a very low ranking deviation. It could in the worst happen that there exist a few ghost vertices in the target graph with very high PageRank, having outgoing edges to only the low rank vertices in the crawl. Our results in figures 3 and 4, on the other hand, support the effectiveness of HAK in most of the studied graphs and therefore also validate our assumptions behind HAK.

We first discuss our findings on synthetic graphs. HAK performs fairly well for $G_{n,p}$, for instance with the BFS crawl strategy with 50% block fraction, we record an absolute error of 0.22 (actual: 0.24, estimated: 0.26) for rank correlation of top 30% vertices. The little ranking deviations in ScaleFree and ForestFire can be attributed to the small crawls with high fidelity ($\gamma \in [0.93, 1.0]$). As already discussed, HAK in these cases would always result in a high value, which also explains HAK adapting to the trends. However, we observe a larger deviation for BFS crawls in ScaleFree graphs. Here, HAK underestimates the ranking deviation, which might reflect the existence of the worst case (caused by the random vertex removal in BFS, cf. Sec. 5.1.3), resulting in a similar estimation as the one described above for very small crawls. However, HAK overestimates the deviation in FFBacklink (see the last 3 plots shown in Figure 4). We attribute this to the fact that the average impact of the crawl increases in presence of backlinks (cp. Sec. 3), which is an overestimation of the actual impact since Forest Fire is nevertheless the dominant topology in this graph. For our measure, a higher average impact corresponds to higher impact on the crawl from the ghost vertices (in our constructed target graph, cp. Sec. 4), leading to increased number of discordant pairs. The uniformly random blocking strategy in the BFS crawls on the other hand might break such backlinks, which lead to a more realistic ranking deviation as well as a better estimation of this deviation by HAK (actual: 0.29, estimated: 0.35).

We report more promising results in case of real-world graphs (s. Fig. 3). For instance, for the UK graph we report an almost precise estimation (actual: 0.58, estimated: 0.61). The observed trend in UK is more similar to that seen in $G_{n,p}$ and FFBacklink, which might also suggest existence of more backlinks in this graph, leading to large cycles (cp. Fig. 2). In contrast, the deviation in Friendster is less strong and slightly overestimated by HAK (actual: 0.76, estimated: 0.66) similar to ForestFire. We remark here that ForestFire also aims to model social networks and we believe that the similarity of these trends might be caused by the scarcity of backlinks in these graphs. We also note that our estimates reflect more closely the ranking deviations among the top PageRank vertices (in either of the compared rankings, cp. Sec. 5.1.4), which we believe to be more interesting for most practical purposes than deviations in less important vertices or the entire graph.
In summary, the effectiveness of HAK is dependent on the fact that how well we estimate the target graph using properties like fidelity. Moreover, we would require big enough crawls to allow for a representative estimation\(^3\) of the target graph. We believe that a more sophisticated use of the fidelity and impact of vertices in crawls, for instance using their distributions instead of simple average, will allow us to estimate the target graph and hence the ranking deviation more accurately. In addition, we plan to investigate more properties of the crawled graph, which can be used to predict the corresponding target graph. As our final goal, we will like to extend HAK as a black-box of measures, from which a suitable measure can be chosen in order to estimate ranking deviations in some particular crawl.

6 CONCLUSION

In this paper, we focused on the problem of PageRank deviations in Web graphs, typically caused by incomplete crawling. We established that deviations in ranking indeed do occur and can be drastic, as shown in our GOV graph where the correlation among the rankings is only 0.55, measured by Kendall’s Tau. To this effect, we proposed the HAK measure, which can reliably estimate such deviations purely on the crawl without any knowledge of the original graph.

Our results suggest that incomplete Web graphs behave surprisingly similar to random graph models and quite different from other generative Web models, such as Forest Fire, in terms of PageRank deviations. Thus, this study on incompleteness in Web graphs could be important in studying the structure of the Web as well. For future work, it would be interesting to check if Web graphs are indeed composed of local random structures. Further, from the insights on the effect of backlinks in this work, we intend to look into other representative formal Web models. Finally, we would like to investigate the applicability of our measure to determine the confidence of results produced by other algorithms on incomplete graphs, such as random walk algorithms similar to PageRank.

A APPENDIX

A.1 Crawling Strategies
- **BFS**: The breadth-first search (BFS) starts from a set of seed vertices and runs until all vertices are reached. A number of vertices according to the block fraction were chosen uniformly at random and blocked/discarded before the BFS, simulating vertices that

\(^3\)We do not want to give recommendations for a minimal size as this is dependent on the target graph and requires some knowledge about it, which should anyway exist when working with a crawl.
We found out that the most realistic seed selection strategy is to pick BfsGeo. We have already created that way in the first place, which proves unimportant vertices (with no in-edges) that were discovered from block fraction from the seed set and run the BFS until the specified desired fraction is discovered. BfsRnd: Similar to BfsRnd, but the number of edges to follow was geometrically distributed with parameter $p = 0.3$, resembling Forrest Fire Sampling [26].

SEC: In this Sample Edge Count strategy [30], at each step the number of edges from the crawled vertices to all remaining vertices are tracked and those with incoming edges are prioritized.

A.2 Seed Selection

We found out that the most realistic seed selection strategy is to pick the most important vertices as seeds. This is also the case for real crawls as these correspond to more well-known pages. To identify such pages in our target graphs, we first ran PageRank on them and constructed the seed set from the top 1%. This allowed us to reduce the size of the large real-world graphs by pre-computing the actual target graphs, consisting only of vertices that are reachable from the seeds (s. Table 1, $V_{target}$ and $E_{target}$). Interestingly, for the GOV and DE graphs, the size difference of the target graphs compared to the originally provided graphs is huge, which confirms common characteristics of these Web archive graphs, i.e., they are not constructed in one crawl, leading to a fairly large number of unimportant vertices (with no in-edges) that were discovered from crawls outside target graphs. The UK and Friendster graphs on the other hand remained at almost the same size, suggesting that they have already been created that way in the first place, which proves our seed selection strategy actually realistic.
